Abstract

**Background and Objectives:** Patients experience moderate to high level of anxiety before cardiac catheterization. This study aimed to investigate the effect of voice of Quran on anxiety before cardiac catheterization.

**Methods:** In this randomized controlled trial, 60 patients who met the inclusion criteria were conveniently sampled and randomly allocated to the experimental and control groups. In the experimental group, patients received 18 minutes of voice of Quran, whereas in the control group, patients had 18 minutes of rest in bed. The level of anxiety was measured immediately before, and immediately after the study using the State-Trait Anxiety Inventory (STAI).

**Results:** Before the study, there was no significant difference between the study groups in terms of the mean score of state and trait anxiety as well as the mean scores of total STAI. However, after the study, the mean scores of state and trait anxiety as well as the mean scores of total STAI in the experimental group were significantly lower than those of the control group.

**Conclusion:** The findings of the study demonstrated that the voice of Quran can significantly improve patients’ anxiety before cardiac catheterization.

**Keywords:** Anxiety, Cardiac catheterization, Cardiovascular system, Voice of Quran.

Introduction

Coronary artery disease is characterized by atherosclerosis in the epicardial coronary arteries. Atherosclerotic plaques, progressively narrow the coronary artery lumen and impair myocardial blood flow (1). The incidence of coronary artery disease has touched alarming proportions. It has almost doubled during the past 3-4 decades (2). According to reports of the American Heart Association (AHA), CVD is a leading cause of death for both men and women (3). One study showed that the CVD, with the incidence of 32%, is the major cause of death in Iran (4). Therefore, early diagnosis of this disease is very important. Cardiac catheterization, as a primary and the gold standard test to diagnose of CAD, are used to evaluate the coronary artery perfusion (5). The AHA reports that in 2007, an estimated 1,061,000 inpatient diagnostic cardiac catheterizations were performed (3). About 18-16 thousand patients annually have undergone cardiac catheterizations, in Iran (6). Despite the benefits of Cardiac catheterizations, it has many complications. One of these complications is...
anxiety. More than 82 percent of patients had fear and anxiety before cardiac catheterizations (7). Anxiety increases blood levels of epinephrine and norepinephrine, resulting in increased blood pressure, heart rate, and myocardial oxygen demand (8, 9).

Many strategies such as sedative-hypnotic agents, have been developed for improving anxiety (10). However, these pharmacological agents are usually associated with adverse effects such as bradycardia, hypotension, gut dysmotility, immobility, weakness, and delirium (11-14). Furthermore, despite protocols provided by clinicians, patients still experience significant levels of anxiety (15, 16). Therefore, the new non-pharmacological treatments are taken into account. Complementary therapies including massage therapy, therapeutic touch, relaxation, aromatherapy, muscle relaxation, and music therapy are effective in reducing anxiety while reducing medication (17-20).

Music therapy is one of the complementary therapies that could improve patients’ anxiety. Music is a powerful destructor that can alter perceived levels of anxiety by occupying attention channels in the brain with meaningful, auditory stimuli rather than stressful environmental stimuli (21). Buffum et al. found that the music therapy reduced patients’ anxiety before cardiac catheterizations (20). Rafieeyan et al. also found that the music therapy decreased patients’ anxiety after caesarean section (22). However, Razavian et al. came to the conclusion that the music therapy had no significant effect on anxiety among patients undergoing root canal therapy (23). In the study by Eckhouse et al., it was found that music therapy had no significant effect on anxiety among patients receiving orthopedic or cancer treatment (24).

The voice of Quran in Islamic countries, including Iran, is considered a mystical music (25). Religious behaviors such as reading Quran could reduce the stress and worries among hospitalized patients (26). Majidi et al. found that the voice of Quran decreased patients' anxiety before cardiac catheterization (27). Ildarabadi et al. also found that the voice of Quran decreased anxiety among patients undergoing open heart surgery (28).

To the best of authors' knowledge, there seems to be a controversy about numerous studies conducted in the area of the effect of listening to the music on patients’ anxiety. Only a limited number specifically evaluate the effect of listening to the voice of Quran on patients’ anxiety. Furthermore, people in different places have different beliefs and may have a different reaction, to hearing the voice of the Quran. Consequently, this study was conducted aiming at investigating the effect of listening to the voice of Quran on anxiety before cardiac catheterization.

**Methods:**

This non-blind randomized controlled trial was conducted in March-April 2015. The study setting was the Cath Lab ward of Beheshti Hospital in Qom, Iran. Sixty patients were conveniently sampled and randomly allocated to the experimental and control groups. The study sample size was calculated using the results of a local study conducted by Kanani et al. Based on the results of Kanani et al. d, and σ were respectively equal to 7.8, and 7. Accordingly, with a type I error probability of 0.05 and a power of 0.80, the sample size was determined to include fifteen patients for each group (29).

The study population comprised all patients hospitalized in the study setting, waiting for cardiac catheterization. The inclusion criteria were being oriented to time, place, and person, no hearing impairments, no known anxiety diseases, no history of resolving psychological drugs, no history of catheterization in each organ and no diseases of the thyroid, adrenal, or pituitary glands (including underactive or overactive). The exclusion criteria included the patient’s reluctance to remain in the study, decreased consciousness, cardiac arrest and using tranquilizers or hypnotic-sedative agents during the study.

The data collection instrument consisted of two parts. The first part included the demographic and clinical information (age, job, living arrangement, educational status, and income) and the second part included the State-
Trait Anxiety Inventory (STAI). The STAI has 40 items. This scale assesses two subscales of trait anxiety and state anxiety each of which 20 themes. Each theme is scored based on 4 points Likert scale (one almost never to four almost always). The total score for each subscales of STAI will be between 20 and 80. Higher scores represent higher anxiety and vice versa individual (30, 31). In this study, a Persian version of STAI was utilized. Validation of the Persian version has yielded satisfactory results. Rabiee et al. and Roohy et al. calculated the Cronbach’s alpha coefficient of 0.89 and 0.90 for the Persian version of STAI, respectively (32, 33).

Firstly, the researcher explained the objectives and methodology of the study to hospital administration, physicians, nurses and the head of the Cath Lab of Beheshti Hospital in Qom, Iran and obtained their consent. Then the researcher attended this unit every day from 7:00 to 19:00 and randomly allocated the patients, who had met the inclusion criteria and signed the consent form, to the experimental and control groups. There are perceived relationships between gender and marital status with levels of anxiety (34-36). Therefore, before allocating the subjects to the two groups, they were matched according to gender and marital status.

After allocating the patients to the experimental and control groups, the researcher extracted all the patients’ demographic and clinical information and entered them in the first part of the instrument. In the experimental group the voice of Quran (Surah Yaseen with the voice of Sheikh Mishary bin Rashid Alafasy) was played back with a headphone for each patient for 18 minutes. The patients in the control group only rested during this period. The level of anxiety was measured in the stages immediately before, and immediately after the study and entered into the second and part of the instrument.

Data were analyzed by using the Statistical Package for Social Sciences (SPSS, v. 11.5). The difference between two groups regarding demographic and clinical data were assessed by independent-samples t-test and the Chi-square tests. The independent-samples t-test was used to assess the effects of voice of Quran on level of anxiety. A p value less than 0.05 was considered statistically significant for all tests.

The Ethics Committee of Qom University of Medical Sciences approved the study. In addition, permissions were obtained from the hospital and Cath Lab authorities. The patients were informed of the aims and the process of the study, being free to participate in the study, or to withdraw from the study at any time, and ensured of the confidentiality of personal information. In addition, a written informed consent was received from each participant.

Results
Thirty patients were enrolled in each group (Fig. 1). The mean age of participants in the experimental and the control groups was 53.63±9.99 and 56.96±7.89 years, respectively. Most of the patients were employed (53.3%), living with their spouses (81.8%), illiterate (55%), and had a moderate income (45%). The results of independent t-test and Chi-square test showed no significant differences in age (P=0.718), job (P=0.301), living arrangement (P=0.1000), educational status (P=0.694), and income (P=0.546) between the two groups (Table 1).

The results of paired t-test showed that in the experimental group, the mean score of state (P=0.301) and trait anxiety as well as the mean scores of total STAI significantly decreased.

after the intervention (P=0.000). However, neither the mean score of state and trait anxiety nor the mean scores of total STAI changed significantly at the end of study in the control group (P = 0.100, 0.368, and 0.967 respectively; Table 2).

The results of the independent t-test for between-group comparison showed that before the study, there was no significant difference between the study groups in terms of the mean score of state and trait anxiety as well as the mean scores of total STAI (P = 0.843, 0.344, and 0.818 respectively). The results of the same test revealed that after the study, the mean scores of state and trait anxiety as well as the mean scores of total STAI in the experimental group were significantly lower than those of the control group (P = 0.000; Table 2).

Discussion:
This study investigated the effect of listening to the voice of Quran on anxiety before cardiac catheterization. The findings revealed that voice of Quran significantly improved the participants’ anxiety. This is in line with the findings of studies conducted by Buffum et al. and Rafieeyan et al. (20, 22). However, Razavian et al. and Eckhouse et al. found that music therapy had no significant effect on participants’ anxiety (23, 24). Razavian and Eckhouse’s difference in results with the current study may be related to differences in methodology of the intervention. In Eckhouse’s study the sample size was much bigger than that of the present study (112 vs. 60). Moreover, the duration of intervention in Razavian’s study was more than that of the present study (total duration of treatment vs. 18 min). Furthermore, in the studies conducted by Razavian et al. and Eckhouse et al. the intervention was the soft music. However, in the current study the intervention was the voice of Quran.

The present study found that the voice of Quran significantly improved state and trait anxiety before cardiac catheterization. In line with the current study, Majidi et al. found that the voice of Quran decreased state and trait anxiety among patients undergoing cardiac catheterization (27). Ildarabadi et al. found that the voice of Quran decreased anxiety among patients undergoing open heart surgery (28). Mirbagher Ajorpaz et al. also reported that the voice of Quran decreased patient’s anxiety before abdominal surgery (25).

In the different parts of the Quran, mention had been made of the relationship between the remembrance of Allah, and reading Quran with relaxation, which reduces anxiety. “We sent down of the Quran that which is a healing and a mercy to believers” (Al-Isra/ 82), “Those who believe, and whose hearts find comfort in the remembrance of Allah, is it not with the remembrance of Allah that hearts are satisfied” (Al-Rad/ 28) (37). It seems that listening to the voice of Quran diverts thoughts from anxiety, pain, and negative experiences to the pleasant thoughts (remembrance of Allah). Therefore, it helped people to cope with emotional stress and decreased their anxiety (25).

This study has several limitations. Different people have different levels of psychological development and hence, different abilities for coping with the strains and pressures. Moreover, different people have different beliefs, which may lead to different reactions to listening to the voice of Quran. These two factors might have affected findings of the present study.

**Conclusion:**
The findings of this study indicate that the voice of Quran can significantly improve anxiety in patients before cardiac catheterization. Accordingly, healthcare providers can use the voice of Quran in combination with current treatments for improving patients’ anxiety. However, conducting further long-term, large-scale studies on patients undergoing cardiac catheterization as well as other patient populations are necessary for providing ample evidence regarding the effectiveness of the voice of Quran in improving the anxiety. Furthermore, comparing the effects of voice of Quran with sedative-hypnotic drugs on patients’ anxiety is also recommended.
